

Task 1: Web Scraping Using Python

Step 1: Accessing the Website

The first step in this task is to access a public website using Python. A request is sent to the website's URL to fetch its HTML content. This allows the program to retrieve the raw webpage data that will be used for scraping.

Step 2: Parsing the HTML Content

Once the webpage content is retrieved, the HTML is parsed using the BeautifulSoup library. Parsing converts the raw HTML into a structured format that can be easily searched and navigated to locate required elements.

Step 3: Identifying and Extracting Relevant Data

In this step, specific HTML elements containing the required information are identified using tags and class attributes. Relevant data such as text content is extracted accurately from these elements.

Step 4: Organizing the Extracted Data

The extracted information is organized into a structured format using Pandas. Rows and columns are created to represent the data clearly, making it suitable for analysis.

Step 5: Creating and Saving the Dataset

Finally, the structured data is saved as a CSV file. This creates a custom dataset that can be reused for further analysis or reporting, completing the web scraping task successfully.
